## Chapter 7

## UNIAXIAL BENDING WITH SHEARING IN STRAIGHT BARS

### 7.1 GENERALS

Bending of straight bars is the result of the action of transversal exterior forces and couples which produce bending moments in cross sections (Fig.7.1). As a consequence of this action, the longitudinal bar axis become curve. The bent bars are called beams.

Fig.7.1
If the forces plan ( $x G z$ or/and $x G y$ ) contains the longitudinal bar axis $x$, reducing the stresses in the centroid G , we shall obtain the bending moments $M_{y}, M_{z}$ and the shear forces $V_{z}$ and $V_{y}$ characteristic to a compound solicitation, represented in cross section with their positive convention (Fig.7.2).

Fig.7.2

We may have simple or compound solicitations:
Uniaxial (straight) bending: only one moment acts in the cross section: $M_{y}$ or $M_{z}$ Biaxial (Oblique) bending: both moments $M_{y}$ and $M_{z}$ act in the cross section Pure bending: when the shear forces in the cross section are missing: $V_{z}=V_{y}=0$; it can be straight or oblique pure bending
Bending with shearing: when all stresses $M_{y}$ and/or $M_{z}, V_{z}$ and/or $V_{y}$ act in the cross section; it can be straight or oblique bending with shearing

## Examples:

a)

A prismatic member subjected to equal and opposite couples acting in the same longitudinal plane. On the entire length the member is subjected to pure bending.
b)

A prismatic member subjected by two equal point forces acting to an equal distance to supports. In this case, only in the central zone (between the loads P) pure bending occurs. On both length " $a$ ' from bar, straight bending with shearing subject the bar. The forces $\mathbf{P}$ act in the forces plan, and the intersection of this plan with the cross section is called the force line (f.l.).

### 7.2 PURE BENDING

The previous example a) is the case of a straight bar subjected to pure bending (only the bending moment $M_{y}$ acts in any cross section of the bar, the sum of the components of the forces in any direction is zero), but only if the bar self-weight is neglected.

For a cross section subjected to pure bending (Fig.7.3), the stresses are:

principal planes

$$
\begin{aligned}
& \underset{\substack{\mathrm{XG} \mathrm{X}\rangle}}{\substack{\text { pincipipal } \\
\text { phane of } \\
\text { the beam }}} \quad N=\int_{A} \sigma_{x} d A=0 \\
& M_{y}=\int_{A} \sigma_{x} d A \cdot z \neq 0 \\
& M_{z}=\int_{A} \sigma_{x} d A \cdot y=0 \\
& V_{z}=V_{y}=0
\end{aligned}
$$

Fig.7.3

### 7.2.1. Geometrical aspect

We shall use the same rubber model as the one used for axial solicitation (centric tension). But in this case the prismatic model will be subjected as in example a) to equal and opposite couples $M_{0}$ (Fig.7.4).

Fig.7.4

The same network of straight lines is traced on the lateral surface of the model. The lines are parallel and equidistant.

Admitting that, what we see on the lateral surface is valid in all the planes which are $\|$ to this surface, instead of vertical lines we discuss about cross sections and instead of longitudinal lines we discuss about longitudinal sections.

After deformation, the longitudinal sections initial straight become curve, they bend uniformly to form a circular arc, the length of the top part decreases and the length of the bottom part increases. The network remains still rectangular because the cross sections initial perpendicular to the longitudinal sections, remain plane and perpendicular to the curved longitudinal section (strips), so the hypothesis of Bernoulli is valid.

Passing from lengthening of the longitudinal strips to their shortening is made continuous on the model height. This means that it will be a longitudinal strip that even if is curved it doesn't change its length. It is a neutral surface that is parallel to the upper and lower surfaces and for which the length does not change. This strip is called neutral strip. The deformed axis of the bent beam is called deformed fiber or line. The intersection between the neutral strip and cross section is called neutral axis.

We observe also that the initial straight angles of the network remain straight after deformation, what means that the specific sliding is null:

$$
\gamma_{x z}=\gamma_{x y}=\gamma_{y z}=0
$$

In what concern the specific elongations $\varepsilon_{x}$, we isolate a differential element from the deformed beam, of length $d x$ (Fig.7.5).

Fig.7.5
On figure $7.5, \rho$ represents the radius of curvature of the neutral strip (constant on $d x$ ) and point $O$ is the center of curvature.

The elementary sections $a-a, b-b$ perpendicular to the longitudinal bar axis before deformation form an elementary angle $d \varphi$ between them, after deformation.

After deformation the neutral strip AB of length $d x$ is curved, but it will have the same length $A B=A^{\prime} B^{\prime}=d x=d s=\rho d \varphi$.

At a level $z$ the lengthening of a fiber can be written from the resemblance of the curvilinear triangles $\mathrm{OA}^{\prime} \mathrm{B}^{\prime}$ and $\mathrm{B}^{\prime} \mathrm{ED}^{\prime}$ :

$$
\frac{\rho}{\mathrm{z}}=\frac{\mathrm{dx}}{\Delta \mathrm{dx}} \rightarrow \Delta d x=\frac{\mathrm{z} \cdot \mathrm{dx}}{\rho}
$$

The specific elongation $\varepsilon_{x}$ :

$$
\varepsilon_{x}=\frac{\Delta \mathrm{dx}}{\mathrm{dx}}=\frac{\mathrm{z}}{\rho} \quad \varepsilon_{x}=\frac{\mathrm{Z}}{\rho}
$$

As, in the above relation of $\varepsilon_{x}$ the coordinate $z$ appear at $1^{\text {st }}$ power, this shows that the strain $\varepsilon_{x}$ varies linearly on cross section, the stresses and strains being negative (compressive) above the neutral plane respectively positive (tension) below it .

The other two strains $\varepsilon_{y}$ and $\varepsilon_{z}$ are neglected:

$$
\varepsilon_{y}=\varepsilon_{z}=-\mu \varepsilon_{x}=-\frac{\dot{\mu}}{\rho} z \cong 0
$$

### 7.2.2. Physical aspect

Admitting that the solicitation takes place in the linear elastic domain, the law of Hooke is valid:

$$
\begin{aligned}
& \sigma=E \cdot \varepsilon \text { and } \tau=G \cdot \gamma \rightarrow \tau_{x z}=\tau_{x y}=\tau_{y z}=0 \\
& \sigma_{x}=\frac{E \cdot z}{\rho} \neq 0
\end{aligned}
$$

$$
\sigma_{y}=\sigma_{z}=0
$$

So, the single distinct unit stress is the normal stress $\sigma_{x}$ which, similarly to the specific strain $\varepsilon_{x}$, varies linearly on the cross section height, being 0 in the neutral axis (n.a.) and maximum (tension and compression) in the extreme fibers. On the bar width, at any level $z, \sigma_{x}$ is constant (uniformly distributed).

The relation of $\sigma_{x}$ can't be yet used, because:

1. We don't know the radius of curvature $\rho$
2. We don't know the position of the neutral axis.

### 7.2.3. The static aspect

We write the stresses from a static calculus (from exterior) and from a strength calculus (from interior). For our solicitation the single stress is $M_{y}=M_{0}$,
the other two (which produce $\sigma_{\mathrm{x}}$ ) $N=M_{z}=0$. These are the stresses from exterior (static). From interior we write the strength definition of these stresses:

1) $N=\int_{A} \sigma_{x} d A=\int_{A} \frac{E z}{\rho} d A=\frac{E}{\rho} \int_{A} z d A=0$

As $\frac{E}{\rho} \neq 0$ ( $\rho$ can't be infinite for $\frac{E}{\rho}=0$, because this means that the bar remains straight) $\Rightarrow S_{y}=\int_{A} z d A=0$ (a)
2) $\begin{aligned} & M_{z}=\int_{A} \sigma_{x} y d A=\int_{A} \frac{E z}{\rho} y d A=\frac{E}{\rho} \int_{A} y z d A=0 \\ &=>I_{y z}=\int_{A} y z d A=0 \text { (b) }\end{aligned}$

Relation (a) shows that the first moment of area $S_{y}$ with respect to the neutral plane is zero. Therefore, the neutral surface must pass through the section centroid, what means that Gy axis is a central axis.

Relation (b) shows that the centrifugal moment of inertia $I_{y z}$ is null, so the system $y G z$ is the principal system. From these two observations, we may conclude that $y G z$ is the principal system of axes, with the origin in the centroid G and the neutral axis is Gy axis (when the force line is $G z$ axis). The vector of the bending moment $M_{y}$ acts along this neutral axis $G y$.
3) $\mathrm{M}_{\mathrm{y}}=\int_{A} \sigma_{x} z d A=\int_{A} \frac{E z}{\rho} z d A=\frac{E}{\rho} \int_{A} z^{2} d A=\frac{\mathrm{E}}{\rho} \mathrm{I}_{\mathrm{y}}=\mathrm{M}_{0}$

$$
\rho=\frac{\mathrm{E}}{\mathrm{M}_{\mathrm{y}}} \mathrm{I}_{\mathrm{y}} \rightarrow \frac{1}{\rho}=\frac{\mathrm{M}_{\mathrm{y}}}{\mathrm{EI}_{\mathrm{y}}} \text { : defines the curvature of deformed longitudinal axis }
$$

Replacing the curvature in the relation of $\sigma_{x}$ :

$$
\sigma_{\mathrm{x}}=\frac{\mathrm{Ez}}{\rho}=\frac{\mathrm{Ez} \mathrm{M}_{\mathrm{y}}}{\mathrm{EI}_{\mathrm{y}}}
$$

Finally we may write the formula of Navier:

$$
\sigma_{\mathrm{x}}=\frac{\mathrm{My}}{\mathrm{Iy}} \mathbf{z} \quad\left[\frac{\mathrm{daN}}{\mathrm{~cm}^{2}}\right]
$$

For a rectangular cross section $\sigma_{\mathrm{x}}$ diagram is:

Fig.7.6

From Navier's relation we may define also the curvature of the neutral surface: $\frac{1}{\rho}=\frac{\mathrm{M}_{\mathrm{y}}}{\mathrm{EI}_{\mathrm{y}}}$, which is in fact a deformation specific to pure bending, representing the relative rotation around the neutral axis of two cross sections situated to a unit distance one from another.

Claude-Louis Navier (1785-1836)
$\mathrm{EI}_{\mathrm{y}}$ : the modulus of rigidity in bending, in [ $\mathrm{daNcm}^{2}$ ]
Navier's formula permit the calculation of the normal stress $\sigma_{x}$ in any point of the cross section including the maximum value of $\sigma_{x}$ (generally this is the most important value of $\sigma_{x}$ in all design problems). The maximum normal stress $\sigma_{x m a x}$ correspond to the maximum coordinate $z_{\text {max }}$. As for the rectangular cross section in the upper and lower fiber the coordinate $z$ are equal but of contrary signs, in these fibers $\sigma_{x}$ will be maximum, one of tension $(+)$ and the other compression $(-)$ :

$$
\sigma_{\mathrm{x} \max }=\frac{\mathrm{M}_{\mathrm{y}}}{\mathrm{I}_{\mathrm{y}}} \mathrm{z}_{\max }=\frac{\mathrm{M}_{\mathrm{y}}}{\frac{\mathrm{I}_{\mathrm{y}}}{\mathrm{z}_{\mathrm{max}}}}
$$

We may define the strength modulus (section modulus):

$$
\mathrm{W}_{\mathrm{y}}=\frac{\mathrm{I}_{\mathrm{y}}}{\mathrm{z}_{\max }}\left[\mathrm{cm}^{3}\right] \quad \text { and } \quad \sigma_{\mathrm{xmax}}=\frac{\mathrm{M}_{\mathrm{y}}}{\mathrm{~W}_{\mathrm{y}}} \text { : another form of Navier's formula }
$$

For some cross sections:

- rectangle:

$$
\mathrm{W}_{\mathrm{y}}=\frac{\mathrm{I}_{\mathrm{y}}}{\mathrm{z}_{\mathrm{max}}}=\frac{\mathrm{bh}^{3}}{12} \frac{2}{\mathrm{~h}}=\frac{\mathrm{bh}^{2}}{6}
$$

- circle:

$$
\mathrm{W}_{\mathrm{y}}=\frac{\pi \mathrm{D}^{4}}{64} \frac{2}{\mathrm{D}}=\frac{\pi \mathrm{D}^{3}}{32}
$$

- I or U profile: $\mathrm{W}_{\mathrm{y}}=\frac{2 \mathrm{I}_{\mathrm{y}}}{\mathrm{h}}$ (given in tables)
- for a simple symmetrical C.S. :

$$
\mathrm{W}_{\mathrm{yb}}=\frac{\mathrm{I}_{\mathrm{y}}}{\mathrm{~h}_{1}}>0 ; \quad \mathrm{W}_{\mathrm{yt}}=\frac{\mathrm{I}_{\mathrm{y}}}{\mathrm{~h}_{2}}<0
$$

### 7.2.4 The rational sections for bent beams

If we observe once again Navier's formula: $\sigma_{x \max }=\frac{\mathrm{My}}{\mathrm{Wy}}$, we may admit that $\sigma_{\mathrm{x}}$ is inversely proportional to the section modulus $W_{y}$ and implicit with the cross section height (in $W_{y}$ the height $h$ for the rectangle is at the second power) This means that the bent beams are recommended to have big heights (if the lateral stability is assured ). Also the distribution of $\sigma_{x}$ on the cross section height shows that the material is efficiently used if the cross section area is concentrated mostly in the extreme fibers.

We can introduce an index of efficiency:

$$
\mathrm{n}=\frac{\mathrm{W}_{\mathrm{y}}}{\mathrm{~A}}=\mathrm{k} \cdot \mathrm{~h}
$$

where: k : is a coefficient that depends on the cross section shape

The greatest coefficient $n$ corresponds to the most economical area, because the consumption of material is proportional to the cross section area. The optimum cross section of a bent bar is a hypothetic section made only from 2 flanges (rectangles). As the thickness of both flanges is very small, the distribution of $\sigma_{x}$ is practically uniform.

$$
\mathrm{I}_{\mathrm{y}} \cong 2 \frac{\mathrm{~A}}{2}\left(\frac{h}{2}\right)^{2}=\frac{\mathrm{Ah}^{2}}{4} \rightarrow \mathrm{~W}_{\mathrm{y}} \cong \mathrm{I}_{\mathrm{y}} \frac{2}{\mathrm{~h}}=\frac{\mathrm{Ah}}{2}
$$

and: $\mathrm{n}=\frac{\mathrm{W}_{\mathrm{y}}}{\mathrm{A}}=\frac{\mathrm{h}}{2}=\mathrm{kh} \rightarrow \mathbf{k}=\mathbf{0 , 5}$
In practice this solution is impossible (without a web to connect the two flanges), and the flanges must be connected by a web.
Ex: - for IPN 400:

$$
\begin{aligned}
& \mathrm{I}_{\mathrm{y}}=29210 \mathrm{~cm}^{4} ; \mathrm{A}=118 \mathrm{~cm}^{4} ; \mathrm{W}_{\mathrm{y}}=1460 \mathrm{~cm}^{3} \\
& \mathrm{n}=\frac{1460}{118}=\mathrm{k} \cdot 40 \rightarrow \mathbf{k}=\mathbf{0 , 3 1}
\end{aligned}
$$

- for a rectangle :

$$
\begin{aligned}
& \mathrm{W}_{\mathrm{y}}=\frac{\mathrm{bh}^{2}}{6} ; \mathrm{A}=\mathrm{bh} \\
& \mathrm{n}=\frac{\mathrm{h}}{6}=\mathrm{k} \cdot \mathrm{~h} \rightarrow \mathbf{k}=\mathbf{0 . 1 7}
\end{aligned}
$$

- for a circle :

$$
\begin{aligned}
& \mathrm{W}_{\mathrm{y}}=\frac{\pi \mathrm{D}^{3}}{32} ; \mathrm{A}=\frac{\pi \mathrm{D}^{2}}{4} \\
& \mathrm{n}=\frac{\mathrm{D}}{8}=\mathrm{k} \cdot \mathrm{D} \rightarrow \mathbf{k}=\mathbf{0 , 1 2 5}
\end{aligned}
$$

The most advantageous cross section for a bent beam is the I profile (it has the biggest coefficient k ), because the area is distributed far off the neutral axis $G y$.

The circular section is very disadvantageous for a bent element because the material is concentrated around the neutral axis, where $\sigma_{x}$ is very small (a lot of material in the weakest subjected zone)

The efficiency of a bent section can be appreciated also by the lever arm of the stresses $h_{0}$ (Fig.7.7) defined as the distance between the resultants of the tensile stresses $T$ and compressive stresses $C$.

Fig.7.7
The two resultants are:

$$
\begin{aligned}
& \mathrm{T}=\int_{A_{t}} \sigma_{\mathrm{x}} \mathrm{dA}=\frac{M_{y}}{I_{y}} \int_{A_{t}} \mathrm{zdA}=\frac{M_{y}}{I_{y}} S_{y t} \\
& \mathrm{C}=\int_{A_{c}} \sigma_{\mathrm{x}} \mathrm{dA}=\frac{M_{y}}{I_{y}} S_{y c}
\end{aligned}
$$

As $G y$ is a central axis, $\mathrm{S}_{\mathrm{y}}=0$ and $\mathrm{S}_{\mathrm{yt}}=-\mathrm{S}_{\mathrm{yc}} \rightarrow \mathbf{T}=-\mathbf{C}$
These resultants form a couple which is exactly the bending moment from section:

$$
\mathrm{M}_{\mathrm{y}}=\mathrm{T} \cdot \mathrm{~h}_{0}=\mathrm{C} \cdot \mathrm{~h}_{0}
$$

The level arm $h_{0}$, is:

$$
\mathrm{h}_{0}=\frac{M_{y}}{T}=\frac{M_{y}}{C}=\frac{I_{y}}{S_{y t}}=\frac{I_{y}}{S_{y c}}
$$

$\mathrm{S}_{\mathrm{yt}}$ and $\mathrm{S}_{\mathrm{yc}}$ : are the first moment of area (static moment) of the tensioned, respectively compressed area - for the ideal section at bending :

$$
\begin{aligned}
& \mathrm{S}_{\mathrm{yt}}=\mathrm{S}_{\mathrm{yc}}=\frac{\mathrm{A}}{2} \frac{\mathrm{~h}}{2}=\frac{\mathrm{Ah}}{4} ; \quad \mathrm{I}_{\mathrm{y}}=\frac{\mathrm{Ah}^{2}}{4} \\
& =>\mathrm{h}_{0}=\frac{I_{y}}{S_{y}}=\mathrm{h}
\end{aligned}
$$

- for the double T cross section IPN 400:

$$
\begin{aligned}
& \mathrm{S}_{\mathrm{yt}}=\mathrm{S}_{\mathrm{yc}}=15,5 \times 2,16 \times 18,92+17,84 \times 1,44 \times 8,92=862,6 \mathrm{~cm}^{3} \\
& \mathrm{~h}_{0}=\frac{29210}{862,6}=33,86 \cong 0,85 \mathrm{~h}
\end{aligned}
$$

- for the rectangular C.S.:

$$
\begin{aligned}
& \mathrm{S}_{\mathrm{yt}}=\mathrm{S}_{\mathrm{yc}}=\mathrm{b} \times \frac{\mathrm{h}}{2} \times \frac{\mathrm{h}}{4}=\frac{\mathrm{bh}^{2}}{8} \\
& \mathrm{~h}_{0}=\frac{\mathrm{bh}^{3}}{12} \times \frac{8}{\mathrm{bh}^{2}}=\frac{2}{3} \mathrm{~h} \cong 0,67 \mathrm{~h}
\end{aligned}
$$

We may conclude that if $h_{0}$ is closer to $h$, the cross section is rational for bending.

### 7.2.5 The main problems of design

In what concern the strength calculation $\left(\sigma_{x}\right)$, the main aspects in designing the bent beams, are:
a) Verification
$\sigma_{\mathrm{x} \text { max }}=\frac{M_{y \text { max }}^{d}}{W_{y}} \leq \mathrm{R}$
with: $\mathrm{M}_{\mathrm{y}}{ }^{\mathrm{d}}=\mathrm{n} \mathrm{M}_{\mathrm{y}}{ }^{\mathrm{k}}$ : is the design bending moment
$\mathrm{M}_{\mathrm{y}}{ }^{\mathrm{k}}$ : is the characteristic bending moment
n : coefficient of loading (partial safety coefficient for load)
b) Dimensioning

$$
\mathrm{W}_{\mathrm{y} \text { nec }} \geq \frac{M_{y \text { max }}^{d}}{R}
$$

c) The bearing capacity at bending (the capable maximum bending moment)
$\mathrm{M}_{\mathrm{y} \text { max }}^{\mathrm{d}} \leq \mathrm{W}_{\mathrm{y}} \times \mathrm{R}$

### 7.3 STRAIGHT BENDING WITH SHEARING

Transverse loading applied to a beam produces normal stresses $\sigma_{x}$, but also shearing stresses $\tau_{\mathrm{x}}$ in transverse cross sections. The normal stresses $\sigma_{x}$ are produced by the bending moments $\mathrm{M}_{\mathrm{y}}$, while the shearing stresses $\tau_{x}$ are produced by the shear force $V_{z}$, when the force line is parallel to $G z$ axis (Fig.7.8) and passes through the shear center $C$. Otherwise, when the force line is parallel to $G y$ axis and passes through the shear center $C$, the normal stresses $\sigma_{x}$ are produced by the bending moments $M_{z}$, while the shearing stresses $\tau_{x}$ are produced (Fig.7.8) by the shear force $V_{y}$. These stresses are represented in the figures bellow, with their positive convention. Now, this is a compound action, but it will be studied separately from each stress.

Fig.7.8
The effect of the bending moment $M_{y}$ was presented in the previous chapter, pure bending, obtaining finally Navier's formula for the normal stress $\sigma_{x}$. The shear force $V_{z}$ will produce a tangential (shear) stress $\tau_{x}$, presented below.

### 7.3.1 Straight shearing (sliding)

### 7.3.1.1 Geometrical aspect

To explain the effect of shear force we consider a model (Fig.7.9) of a bar loaded in such manner so that a part of the bar is subjected to pure bending and the rest at bending with shearing (example b.) from the first paragraph).

Fig.7.9

Considering that the network from the lateral surface of the model is valid inside the model, we observe:

1. a supplementary increasing of the curvature of the longitudinal lines, but with a small quantity (approximately $5 \%$ from the curvature produced by the bending moment $\mathrm{M}_{\mathrm{y}}$ )
2. in the central zone of length " $l-2 a$ " the cross sections remain plane and perpendicular to the longitudinal curved fibers.
3. in the marginal zones of length " $a$ " subjected to bending with shearing, the cross sections are distorted, becoming

4. analyzing a rectangle from network from this zone of length " $a$ ", we remark that the distortion is introduced by angular deformations (specific sidings) $\gamma_{x z}$ in plan parallel to $x G z$ plan, the initial straight angles being modified with:

$$
\gamma_{x z}=\gamma_{\mathrm{t}}+\gamma_{1}
$$

$\gamma_{\mathrm{t}}$ : is produced by the relative transversal sliding of the cross section
$\gamma_{1}$ : is produced by the relative longitudinal sliding of the longitudinal fibers parallel to the neutral surface (strip)
We may observe from model that the specific sliding $\gamma_{x z}$ isn't constant on the cross section height, being maximum in the neutral strip and zero in the extreme fibers, where the straight angle was maintained.

But, on the height of the cross section the specific sliding $\gamma_{x z}$ has an unknown distribution, as well as on the cross section width. But, as to any level $z$, the tangent to the directories has the same inclination the specific sliding is constant on the cross section width.

### 7.3.1.2 Physical aspect

A material with a linear-elastic behaviour is considered, where Hooke's law is valid: $\tau_{\mathrm{xz}}=\mathrm{G} \times \gamma_{\mathrm{xz}}$

So, the shear stresses $\tau_{x z}$ have the same distribution as $\gamma_{x z}$, being constant on the cross section width at any level $z$, but with an unknown variation on the cross section height. Representing the constant distribution of $\tau_{x z}$ in the cross section plan, we may admit in accordance to the duality law that shear stresses $\tau_{\mathrm{zx}}\left(\tau_{\mathrm{xz}}=\right.$ $\tau_{\mathrm{zx}}$ ) will also exist, in longitudinal plans which are parallel to the neutral strip (Fig.7.10). Longitudinal shearing stresses must exist in any member subjected to transverse loading.

Fig.7.10
These two complementary stresses $\tau_{x z}$ and $\tau_{z x}$ correspond to 2 types of sliding: transversal sliding and longitudinal sliding. Shorter we'll say that $\tau_{x z}$ produces shearing and $\tau_{z x}$ produces sliding.

### 7.3.1.3 Static aspect

The shear force $\mathrm{V}_{\mathrm{z}}$ from static calculation is: $\mathrm{V}_{\mathrm{z}}{ }^{\text {st }}=\mathrm{P}$
From strength calculation, $\mathrm{V}_{\mathrm{z}}$ is: $\mathrm{V}_{\mathrm{z}}^{\text {res }}=\int_{A} \tau_{x z} d A$, unknown because the distribution of $\tau_{x z}$ is unknown on the cross section height.

That's why we have to search another cross section on which the shear stress distribution is known.

### 7.3.1.4 Formula of Juravski

We'll consider a bar loaded by a system of forces acting perpendicularly to the axis and comprised in the longitudinal symmetry plan of the bar (Fig.7.11).

Fig.7.11
We may consider a constant distribution of $\tau_{x z}$ on a differential element of length $d x$, situated to a level $z$ from the neutral strip (Fig.7.12).

Fig.7.12

According to the method of sections, the effect of the removed part is introduced by the stresses acting on the differential element. So, on the transversal sections we dispose the normal stresses $\sigma_{x}$ and the shear stresses $\tau_{x z}$, while on the longitudinal section at level $z$ we dispose the sliding stresses $\tau_{z x}$.

To write equations of static equilibrium for this differential element, first we have to write the resultants of the stresses acting on the differential element.

At a level $\eta$ the normal stress $\sigma_{x}$ is:

$$
\sigma_{\mathrm{x}}=\frac{M_{y}}{I_{y}} \cdot \eta
$$

and the resultant:

$$
\mathrm{T}=\int_{A_{z}} \sigma_{x} d A=\frac{M_{y}}{I_{y}} \int_{A_{z}} \eta \cdot d A=\frac{M_{y}}{I_{y}} S_{y}(z)
$$

where: $S_{y}(z)$ : is the static moment, written about the neutral axis $G y$, of the section $A_{z}$ situated to a level $z$, called calculus level.

The differential resultant dT is (if the cross section of the bar is constant):

$$
\mathrm{dT}=\mathrm{d}\left(\frac{M_{y}}{I_{y}} S_{y}(z)\right)=\frac{S_{y}(z)}{I_{y}} d M_{y}=\frac{S_{y}(z)}{I_{y}} V_{z} d x
$$

where: $\mathrm{dM}_{\mathrm{y}}=\mathrm{V}_{\mathrm{z}} \mathrm{dx}$, from the second differential relation between stresses.
The resultant of the sliding stress $\tau_{z x}$ is:

$$
\mathrm{dL}_{\mathrm{z}}=\tau_{\mathrm{zx}} \cdot \mathrm{~b}_{\mathrm{z}} \cdot \mathrm{dx}
$$

We write an equation of static equilibrium along the bar axis:
$\boldsymbol{\Sigma} \mathrm{X}=0: \quad-\mathrm{T}+\mathrm{T}+\mathrm{dT}-\mathrm{dL}_{\mathrm{z}}=0 \Rightarrow \mathrm{dT}=\mathrm{dL}_{\mathrm{z}}$
Replacing:

$$
\begin{aligned}
\frac{S_{y}(\bar{z})}{I_{y}} V_{z} \mathrm{dx} & =\tau_{\mathrm{zx}} \mathrm{~b}_{\mathrm{z}} \mathrm{dx}, \text { but } \tau_{\mathrm{zx}}=\tau_{\mathrm{xz}} \\
\tau_{\mathrm{xz}} & =\frac{V_{z} \boldsymbol{S}_{y}(\mathrm{z})}{\boldsymbol{b}_{z} I_{y}} \quad \text { Juravski's formula }
\end{aligned}
$$

The formula shows that the shear stresses $\tau_{x z}$ are proportional to the shear force $V_{z}$ and they have the same orientation as $V_{z}$, in cross section. The distribution of $\tau_{x z}$ on the cross section height is given by the variation of the ratio $\frac{\mathrm{S}_{\mathrm{y}}(\mathrm{z})}{\mathrm{b}_{\mathrm{z}}}$. As in the extreme fibers $\mathrm{S}_{\mathrm{y}}(\mathrm{z})=0$, the shear stress $\tau_{x z}$ is also null.

### 7.3.1.5 Juravski's formula for the narrow rectangular section

A rectangular section is narrow, from shear point of view, if: $\frac{h}{b} \geq 2$
At a level $z$, the static moment (Fig.7.13) is:
$S_{y}(z)=b\left(\frac{h}{2}-z\right)\left(z+\frac{h}{4}-\frac{\mathrm{z}}{2}\right)=b\left(\frac{h}{2}-z\right)\left(\frac{\mathrm{z}}{2}+\frac{\mathrm{h}}{4}\right)=\frac{\mathrm{b}}{2}\left(\frac{\mathrm{~h}}{2}-\mathrm{z}\right)\left(\frac{\mathrm{h}}{2}+\mathrm{z}\right)=\frac{\mathrm{b}}{2}\left(\frac{\mathrm{~h}^{2}}{4}-\mathrm{z}^{2}\right)$

Fig.7.13
The shear stress:
$\left.\tau_{\mathrm{xz}}=\frac{V_{z} S_{y}(z)}{b_{z} I_{y}}=\frac{V_{z} \frac{\mathrm{~b}}{2}\left(\frac{\mathrm{~h}^{2}}{4}-\mathrm{z}^{2}\right)}{\mathrm{b} \frac{\mathrm{bh}^{3}}{12}}=\frac{6 V_{z}}{\mathrm{bh}^{3}} \frac{\mathrm{~h}^{2}}{4}-\mathrm{z}^{2}\right)$
The above expression shows that $\tau_{\mathrm{xz}}$ has a parabolic variation on the cross section height.

For $\mathrm{z}= \pm \frac{\mathrm{h}}{2} \Rightarrow \tau_{\mathrm{xz}}=0$
For $\mathrm{z}=0 \Rightarrow \tau_{\mathrm{xz} \max }=\frac{6 V_{Z}}{\mathrm{bh}}{ }^{\frac{h^{2}}{2}} \frac{3}{4}=\frac{V_{z}}{2} \frac{V_{z}}{\mathrm{bh}}$
$\tau_{\mathrm{xz} \text { max }}=\mathbf{1 , 5} \frac{V_{z}}{\mathrm{~A}} \quad$ For the rectangular cross section the maximum shear stress from shearing with bending is with $50 \%$ bigger that the medium stress $\frac{V_{Z}}{A}$ from pure shearing.

### 7.3.1.6 Juravski's formula for a double $T$ cross section, made from narrow rectangles

From previous paragraph we may remark that for a narrow rectangle the shear stresses are always orientated along the longest side of the rectangle. This observation is also valid for the cross sections made from narrow rectangles (the rolled, laminated profiles), the shear stresses $\tau_{x}$ being orientated along the biggest side of each rectangle, whatever is the relative position between this side and the force line. In accordance to this observation, in a double $T$ cross section $\tau_{x z}$ will exist in web (the longest side of the web is parallel to $G z$ axis), while in flanges a shear stress $\tau_{x y}$ will appear (the flange is parallel to Gy axis)

Let's consider a double symmetrical I section (Fig.7.14), subjected to straight shearing by a positive shear force $V_{z}>0$.

Fig. 7.14

$$
S_{y}(z)=b t\left(\frac{h}{2}+\frac{\mathrm{t}}{2}\right)+\mathrm{d}\left(\frac{\mathrm{~h}}{2}-\mathrm{z}\right)\left(\frac{\mathrm{h}}{4}-\frac{\mathrm{z}}{2}+\mathrm{z}\right)=\frac{\mathrm{bt}}{2}(\mathrm{~h}+\mathrm{t})+\frac{\mathrm{d}}{2}\left(\frac{\mathrm{~h}^{2}}{4}-\mathrm{z}^{2}\right)
$$

$$
\tau_{\mathrm{xz}}(\mathrm{z})=\frac{\mathrm{V}_{\mathrm{z}}}{2 \mathrm{dI}_{\mathrm{y}}}\left[\mathrm{bt}(\mathrm{~h}+\mathrm{t})+\mathrm{d}\left(\frac{\mathrm{~h}^{2}}{4}-\mathrm{z}^{2}\right)\right]
$$

The expression of $\tau_{x z}$ is mathematically a parabola of second degree, so in web the shear stress $\tau_{x z}$ parallel to $z$ will have a parabolic variation. The maximum value will correspond to $\mathrm{z}=0$ (in the neutral axis):

$$
\tau_{\mathrm{xz}}(\mathrm{z})=\frac{\mathrm{T}_{\mathrm{z}}}{2 \mathrm{dI}_{\mathrm{y}}}\left[\mathrm{bt}(\mathrm{~h}+\mathrm{t})+\frac{d h^{2}}{4}\right]
$$

and, for $\mathrm{z}= \pm \frac{\mathrm{h}}{2}$ :

$$
\tau_{\mathrm{xz}}(\mathrm{z})=\frac{\mathrm{T}_{\mathrm{z}}}{2 \mathrm{dI}_{\mathrm{y}}} \mathrm{bt}(\mathrm{~h}+\mathrm{t}) \text {, a smaller value }
$$

So, the shear stress $\tau_{x z}$ is drawn on the cross section web (parallel to $z$ axis), it has a parabolic variation on the web height and with a maximum value in the neutral axis. As the thickness $t$ of the rectangle is very small we admit that the shear stresses $\tau_{x}$ are uniformly distributed on thickness (it is constant), and their resultant $\tau_{x} \times t$ is called shearing flow. To explain the shearing flow in a thinwalled section, we start from $\tau$ from web $\left(\tau_{x z}\right)$ which has the same direction as $V_{z}$ and then a hydrodynamic analogy is made considering that the section is a thinwalled tube and a liquid must flow through it.

In flange, at the level $\xi$ :

$$
S_{y}(\xi)=\xi t\left(\frac{h}{2}+\frac{t}{2}\right)
$$

$$
\tau_{\mathrm{xy}}(\xi)=\frac{\mathrm{V}_{\mathrm{z}}}{2 \mathrm{I}_{\mathrm{y}}} \xi(\mathrm{~h}+\mathrm{t}) \Rightarrow \tau_{\mathrm{xy}} \text { has a linear variation }
$$

For $\xi=0 \Rightarrow \tau_{\mathrm{xy}}=0$
For $\xi=\frac{\mathrm{b}-\mathrm{d}}{2}=>\tau_{\mathrm{xy}}=\frac{\mathrm{V}_{\mathrm{z}}(\mathrm{b}-\mathrm{d})(\mathrm{h}+\mathrm{t})}{4 \mathrm{I}_{\mathrm{y}}}$

### 7.3.1.7. Juravski's formula for a tubular cross section, made from narrow rectangles

We consider a double symmetrical tubular (caisson) cross section (Fig.7.15).
The static moments:

$$
\begin{aligned}
& S_{y}(z)=b t\left(\frac{h}{2}-\frac{t}{2}\right)+2\left(\frac{h}{2}-t-z\right) d\left(\frac{h}{4}-\frac{t}{2}-\frac{z}{2}+z\right)=\frac{b t}{2}(h-t)+\left[\left(\frac{h}{2}-t\right)^{2}-z^{2}\right] d \\
& b_{z}=2 d \\
& S_{y}(\xi)=\frac{t \xi}{2}(h-t) \\
& b_{z}(\xi)=t
\end{aligned}
$$

The shear stress at the level $z$ :

$$
\tau_{\mathrm{xz}}(\mathrm{z})=\frac{\mathrm{V}_{\mathrm{z}}}{2 \mathrm{dI}_{\mathrm{y}}}\left\{\frac{\mathrm{bt}}{2}(\mathrm{~h}-\mathrm{t})+\left[\left(\frac{h}{2}-t\right)^{2}-z^{2}\right] \mathrm{d}\right\}
$$

The shear stress at the level $\xi$ :

$$
\tau_{\mathrm{xy}}(\xi)=\frac{\mathrm{v}_{\mathrm{z}}}{2 \mathrm{I}_{\mathrm{y}}} \xi(\mathrm{~h}-\mathrm{t})
$$

In the symmetry axis $G z$, when the shear force $V_{z}$ acts along it, $\tau_{\mathrm{xy}}=0$

Fig.7.15

### 7.3.2 Longitudinal sliding

### 7.3.2.1 The longitudinal force of sliding

In the previous paragraph, we have seen that in accordance to duality law, tangential (sliding) stress $\tau_{\mathrm{zx}}$ will also exist in plans that are parallel to the neutral surface, called shorter sliding stresses $\tau_{\mathbf{z x}}$. On a length of beam, their resultant is called force of sliding.

We can explain very simple the existence of these sliding forces, considering a composed beam made from 2 superposed elements (a).

b)

In the first situation we admit that the 2 elements aren't connected (b). Each element is deformed separately, generating
 separately the typical linear variation of normal stress $\sigma_{\mathrm{x}}$ over its own depth. The contact surfaces will slide one with respect to the other.

Now, considering the elements are connected between them, both elements respond as a unit (c). Bending stresses will now vary linearly over the whole depth. The relative sliding of the contact surfaces is prevented, along these surfaces appearing sliding forces.

To evaluate the sliding force, we start from the differential sliding force $d L_{z}$ used in the demonstration of Juravski's formula:

$$
\mathrm{dL}_{\mathrm{z}}=\tau_{\mathrm{zx}} \mathrm{~b}_{\mathrm{z}} \mathrm{dx} \text {, at a calculus level } z
$$

but: $\quad \tau_{\mathrm{zx}}=\frac{V_{z} S_{y}(z)}{b_{z} I_{y}}$
and: $\mathrm{dL}_{z}=\frac{V_{z} S_{y}(\mathrm{z})}{I_{y}} \mathrm{dx}$
On a finite interval, between $\mathrm{x}_{2}$ and $\mathrm{x}_{1}$, from integration, the sliding force is:

$$
\mathrm{L}_{\mathrm{z}}=\int_{\mathrm{x}_{1}}^{\mathrm{x}_{2}} \mathrm{dL}_{\mathrm{z}}=\int_{\mathrm{x}_{1}}^{\mathrm{x}_{2}} \frac{V_{z} S_{y}(\mathrm{z})}{I_{y}} \mathrm{dx}
$$

If the cross section is constant on the length $\mathrm{e}=\mathrm{x}_{2}-\mathrm{x}_{1}$, the ratio $\frac{S_{y}(z)}{I_{y}}=$ const.

$$
\mathrm{L}_{\mathrm{z}}=\frac{s_{y}(z)}{I_{y}} \int_{\mathrm{x}_{1}}^{\mathrm{X}_{2}} \mathrm{~V}_{\mathrm{z}} \mathrm{dx}
$$

With: $\mathrm{dM}_{\mathrm{y}}=\mathrm{V}_{\mathrm{z}} \cdot \mathrm{dx}=>$

$$
\mathrm{L}_{\mathrm{z}}=\frac{s_{y}(z)}{I_{y}} \int_{\mathrm{x}_{1}}^{\mathrm{x}_{2}} \mathrm{dM}_{\mathrm{y}}=\frac{\mathrm{Sy}(\mathrm{z})}{\mathrm{Iy}}\left(\mathrm{M}_{\mathrm{y} 2}-\mathrm{M}_{\mathrm{y} 1}\right)
$$

If the distance: $e=x_{2}-x_{1}$ is small we may consider a constant distribution of the shear force $V_{z}$ on this distance, and:

$$
\begin{array}{r}
\mathrm{L}_{\mathrm{z}}=\frac{S_{y}(z)}{I_{y}} \mathrm{~V}_{\mathrm{z}} \int_{\mathrm{X}_{1}}^{\mathrm{X}_{2}} \mathrm{dx}=\frac{S_{y}(z)}{I_{y}} \mathrm{~V}_{\mathrm{z}}\left(\mathrm{X}_{2}-\mathrm{X}_{1}\right)=> \\
\mathbf{L}_{\mathbf{z}}=\frac{S_{y}(\mathrm{z}) \mathrm{V}_{\mathrm{z}}}{I_{y}} \mathbf{e}
\end{array}
$$

In this formula:
$\mathrm{S}_{\mathrm{y}}(\mathrm{z})$ is the static moment of the area that slides longitudinally, admitting that we neglect the connection elements (rivets, bolts, welding).
e : the longitudinal distance between these elements (rivets)

### 7.3.2.2 The elements of connection

We discuss the case of a composed I section, connected with rivets through 4 angles with equal legs. The angles are connected to web by grove rivets (1)

and to flanges by head rivets (2). From constructive reasons, the diameters of both types of rivets are taken identically, but the head rivets are placed in sections situated to a semi distance (e/2) from the sections with groove rivets (to avoid a greater diminishing of the cross section due to the rivets holes)

In the formula of $L_{z}$, the static moment $S_{y}(z)$ is taken :

- for head rivets (2) :

$$
\mathrm{S}_{\mathrm{y}}\left(\mathrm{Z}_{2}\right)=\mathrm{A}_{2} \mathrm{Z}_{2}
$$

- for grove rivets (1):

$$
\mathrm{S}_{\mathrm{y}}\left(\mathrm{z}_{1}\right)=\mathrm{A}_{1} \mathrm{z}_{1}>\mathrm{S}_{\mathrm{y}}\left(\mathrm{z}_{2}\right)
$$

As $S_{y}$ for the grove rivets (1) is bigger: $S_{y}\left(z_{1}\right)>S_{y}\left(z_{2}\right)$ the sliding force is also bigger $L_{z 1}>L_{22}$, so it is sufficient if we compute only these rivets (1):
$\mathrm{L}_{\mathrm{z} 1}=\frac{s_{y}(z 1) \mathrm{V}_{\mathrm{z}}}{I_{y}} \mathrm{e}$
This sliding force, which corresponds to one rivet, must not exceed the minimum stress (force) which can be transmitted by one rivet, representing the minimum between the stress corresponding to the rivet shearing, respectively the stress corresponding to the local pressure:

$$
\begin{aligned}
& \mathrm{N}_{\text {min }}=\min \left(\mathrm{N}_{\mathrm{f}}, \mathrm{~N}_{\mathrm{p}}\right) \\
& \mathrm{N}_{\mathrm{f}}=\mathrm{n}_{\mathrm{f}} \frac{\pi \mathrm{~d}^{2}}{4} 0.8 \mathrm{R} \\
& \mathrm{~N}_{\mathrm{p}}=\mathrm{d}(\Sigma \mathrm{t})_{\min } 2 \mathrm{R}
\end{aligned}
$$

So, the condition is:

$$
\mathrm{L}_{\mathrm{z} 1} \leq \mathrm{N}_{\min } \quad \Rightarrow \quad \mathrm{e} \leq \frac{N_{\min } I_{y}}{V_{z} S_{y}\left(z_{1}\right)}
$$

where: $\mathrm{I}_{\mathrm{y}}$ and $\mathrm{S}_{\mathrm{y}}\left(\mathrm{z}_{1}\right)$ are taken with their gross values (without diminishing)
Supplementary, there are constructive measures given in standards, which impose:

$$
\begin{aligned}
& \mathrm{e} \leq 8 \mathrm{~d} \\
& \mathrm{e} \leq 12 \mathrm{t}
\end{aligned}
$$

where : d: the rivet (bolt) diameter
t : the minimum thickness of the elements connected with rivets (bolts)

### 7.4. THE CALCULATION OF DEFLECTIONS DUE TO UNIAXIAL BENDING

### 7.4.1. Basis of design

Let's consider a simple supported beam subjected to uniaxial (straight) bending (fig.7.16).

Fig.7.16
The beam is represented in a deformed shape, the main deformations being inscribed on figure.

Admitting the hypothesis of the small deformations, the calculation of these deformations is made on the undeformed shape of the bar (calculus of first order) and we shall admit that we have only vertical displacements $\boldsymbol{w}$, called deflections (the longitudinal displacement $u$ of the mobile support is neglected and horizontal component of the displacement $u_{k}$ is also neglected in comparison with the
deflection $w_{k}$ ). Also, in time of deformation, the cross sections are rotating around the neutral axis $G y$, producing the rotation $\varphi_{y}$, which is equal to the angle between the horizontal and the tangent to the deformed shape of the beam.

The displacement (deflections and rotations) of the cross section can be calculated by two main methods:

- methods that use the differential equation of the deformed axis (fiber)
- energetically methods (studied later)
7.4.2 The analytical calculation of the displacements integrating the differential equation of the deformed axis (Direct integration of the equation of the elastic curve)

From analytical geometry, the expression of the curvature of a plane curve (a) is:

$$
\frac{1}{\rho}=\frac{\frac{d^{2} y}{d x^{2}}}{\left[1+\left(\frac{d y}{d x}\right)^{3}\right]^{3 / 2}}
$$

b)

For a curved bar (b) the curvature can be written:

$$
\frac{1}{\rho}=\frac{\frac{d^{2} w}{d x^{2}}}{\left[1+\left(\frac{d w}{d x}\right)^{2}\right]^{3 / 2}}
$$

In practice the deformed fiber (axis) has a very small curvature and the first
 derivative of the deflection $w$ can be assimilated to the rotation $\varphi$ :

$$
\frac{d w}{d x}=w^{\prime}=\operatorname{tg} \varphi \cong \varphi
$$

With this, the curvature in the above relation: $\frac{1}{\rho}=\frac{\frac{\mathrm{d}^{2} w}{d \mathrm{x}^{2}}}{\left(1+\varphi^{2}\right)^{3 / 2}}$
But, the rotation $\varphi$, expressed in radian, has always a very small value, so the square of $\varphi$ in this relation can be neglected. With this simplification, the curvature is:
$\frac{1}{\rho}=\frac{d^{2} \mathrm{w}}{\mathrm{dx}^{2}}=\mathrm{w} "$
But, from pure bending we know that the relationship between bending moment and curvature remains valid for general transverse loadings:
$\frac{1}{\rho}=\frac{M_{y}}{E I_{y}}$
Between the curvature $\frac{1}{\rho}$ and the bending moment $M_{y}$, a sign convention is considered: the curvature is positive if the curvature center $C_{\rho}$ is situated towards positive $z$ axis:

In conclusion: the curvature $\frac{1}{\rho}$ and the bending moment will always have

## different signs.

From this observation we may write now correct the relationship between bending moment and curvature, obtained in paragraph 7.2.3:

$$
\frac{1}{\rho}=-\frac{\text { My }}{\text { EIy }}
$$

Identifying these two expressions of the curvature we write finally the differential equation of the deformed axis (equation of the elastic curve):

$$
\frac{d^{2} w}{d x^{2}}=w "=-\frac{M y}{E I y} \quad \text { where: } E I_{y} \text { is the modulus of rigidity for bending }
$$

Integrating once, the rotation $\varphi$ is obtained:

$$
\frac{\mathrm{dw}}{\mathrm{dx}}=\varphi=-\int \frac{M_{y}}{E I_{y}} d x+\mathrm{C}_{1}
$$

Integrating once again, the deflection $\boldsymbol{w}$ is obtained:

$$
\mathrm{w}=-\int d x \int \frac{M_{y}}{E I_{y}} d x+\mathrm{C}_{1} \mathrm{x}+\mathrm{C}_{2}
$$

The constants of integration $\mathrm{C}_{1}$ and $\mathrm{C}_{2}$ can be calculated from boundary conditions written in supports, or from continuity conditions.

Boundary conditions:

- for simple (mobile) support or for hinge: $\mathbf{w}(\mathbf{0})=\mathbf{0}, \varphi(0) \neq 0$

- for a built-in (fixed) support: $\mathrm{w}(0)=0, \varphi(0)=0$

The continuity conditions take account the fact that the deformed shape of the bar must remain a continuous function and with continuous derivatives.

- the continuity conditions:
$W_{D_{s t}}=W_{D_{d r}}$ and $\quad \varphi_{\text {Dst }}=\varphi_{\text {Ddr }}$

To integrate the differential equation $\frac{d^{2} w}{d x^{2}}=-\frac{M y}{\text { Ely }}$, the function $M_{y}(x)$ must be continuous and with continuous derivatives.

## Examples:

For the cantilever loaded by the concentrate force Pacting in the free end:

$M_{y}(x)=-P(l-x) \quad$ which is introduced in the equation of the elastic curve:

$$
\frac{d^{2} w}{d^{2}}=-\frac{M y}{E I y}
$$

$$
\frac{\mathrm{dw}}{\mathrm{dx}}=\varphi=\int \frac{P(l-x)}{E I_{y}} d x=\frac{P l}{E I_{y}} x-\frac{P}{E I_{y}} \frac{x^{2}}{2}+c_{1}
$$

$\mathrm{w}=-\int d x \int \frac{M_{y}}{E I_{y}} d x=\frac{P l}{E I_{y}} \frac{x^{2}}{2}-\frac{P}{E I_{y}} \frac{x^{3}}{6}+c_{1} x+c_{2}$
Writing the boundary conditions in the built-in support:
$w(0)=0$ and $\varphi(0)=0 \rightarrow c_{1}=c_{2}=0$
The analytical expressions of the deflection $\mathrm{w}(\mathrm{x})$ and rotation $\varphi(\mathrm{x})$ are:
$\mathrm{w}(\mathrm{x})=\frac{P l}{E I_{y}} \frac{x^{2}}{2}-\frac{P}{E I_{y}} \frac{x^{3}}{6}$ and $\varphi(\mathrm{x})=\frac{P l}{E I_{y}} x-\frac{P}{E I_{y}} \frac{x^{2}}{2}$
Their maximum values are in the free end of the cantilever, so for $\mathrm{x}=1$ :
$w_{\text {max }}=\frac{P l^{3}}{3 E I_{y}}$ and $\varphi_{\text {max }}=\frac{P l^{2}}{2 E I_{y}}$

For the cantilever loaded by the uniformly distributed force $q$ on the entire length:

$$
M_{y}(x)=-q \frac{(l-x)^{2}}{2} \quad \text { which } \quad \text { is }
$$

introduced in the equation of the elastic curve:

$$
\frac{\mathrm{d}^{2} w}{\mathrm{dx}^{2}}=-\frac{\mathrm{My}}{\mathrm{EIy}}
$$

$$
\begin{aligned}
& \frac{\mathrm{dw}}{\mathrm{dx}}=\varphi=\int q \frac{(l-x)^{2}}{2} d x=\frac{q l^{2}}{2 E I_{y}} x-\frac{q l}{E I_{y}} \frac{x^{2}}{2}+\frac{q}{2 E I_{y}} \frac{x^{3}}{3}+c_{1} \\
& \mathrm{w}=-\int d x \int \frac{M_{y}}{E I_{y}} d x=\frac{q l^{2}}{2 E I_{y}} \frac{x^{2}}{2}-\frac{q l}{E I_{y}} \frac{x^{3}}{6}+\frac{q}{2 E I_{y}} \frac{x^{4}}{12}+c_{1} x+c_{2}
\end{aligned}
$$

Writing the boundary conditions in the built-in support:
$w(0)=0$ and $\varphi(0)=0 \rightarrow c_{1}=c_{2}=0$
The analytical expressions of the deflection $\mathrm{w}(\mathrm{x})$ and rotation $\varphi(\mathrm{x})$ are:
$\mathrm{w}(\mathrm{x})=\frac{q l^{2}}{2 E I_{y}} \frac{x^{2}}{2}-\frac{q l}{E I_{y}} \frac{x^{3}}{6}+\frac{q}{2 E I_{y}} \frac{x^{4}}{12}$ and $\varphi(\mathrm{x})=\frac{q l^{2}}{2 E I_{y}} x-\frac{q l}{E I_{y}} \frac{x^{2}}{2}+\frac{q}{2 E I_{y}} \frac{x^{3}}{3}$
Their maximum values are in the free end of the cantilever, so for $\mathrm{x}=1$ :
$w_{\max }=\frac{q l^{4}}{8 E I_{y}}$ and $\varphi_{\max }=\frac{q l^{3}}{6 E I_{y}}$
For the simple supported beam loaded by the uniformly distributed force $q$ on the entire length:

$M_{y}(x)=\frac{q l}{2} x-q \frac{x^{2}}{2} \quad$ which $\quad$ is introduced in the equation of the elastic curve:

$$
\frac{d^{2} w}{d x x^{2}}=-\frac{M y}{\text { EIy }}
$$

$$
\frac{\mathrm{dw}}{\mathrm{dx}}=\varphi=\int\left(-\frac{q l}{2} x+q \frac{x^{2}}{2}\right) d x=-\frac{q l}{2 E I_{y}} \frac{x^{2}}{2}+\frac{q}{E I_{y}} \frac{x^{3}}{6}+c_{1}
$$

$\mathrm{W}=-\int d x \int \frac{M_{y}}{E I_{y}} d x=-\frac{q l}{2 E I_{y}} \frac{x^{3}}{6}+\frac{q}{E I_{y}} \frac{x^{4}}{24}+c_{1} x+c_{2}$
Writing the boundary conditions in the simple support and in hinge:
$w(0)=0$ and $w(l)=0 \rightarrow c_{2}=0$ and $c_{1}=\frac{q l^{3}}{24 E I_{y}}$
The analytical expressions of the deflection $\mathrm{w}(\mathrm{x})$ and rotation $\varphi(\mathrm{x})$ are:

$$
\mathrm{w}(\mathrm{x})=-\frac{q l}{2 E I_{y}} \frac{x^{3}}{6}+\frac{q}{E I_{y}} \frac{x^{4}}{24}+\frac{q l^{3}}{24 E I_{y}} x \text { and } \varphi(\mathrm{x})=-\frac{q l}{2 E I_{y}} \frac{x^{2}}{2}+\frac{q}{E I_{y}} \frac{x^{3}}{6}+\frac{q l^{3}}{24 E I_{y}}
$$

The maximum value of the deflection is in the middle span of the beam, so for $\mathrm{x}=\frac{l}{2}$ :
$w_{\max }=\frac{5}{384} \frac{q l^{4}}{E I_{y}}$ and the corresponding rotation $\varphi\left(\frac{l}{2}\right)=0$
The maximum value of the deflection is in the beam supports, so for $\mathrm{x}=0$ or $\mathrm{x}=\mathrm{l}$ :

$$
\varphi_{\max }= \pm \frac{q l^{3}}{24 E I_{y}}
$$

If $M_{y}$ diagram isn't continuous, the integration must be done on each interval of continuity.

Example:

$$
\begin{aligned}
& M_{1}\left(x_{1}\right)=\frac{P b}{l} x_{1} \\
& M_{2}\left(x_{2}\right)=\frac{P b}{l} x_{2}-P\left(x_{2}-a\right)
\end{aligned}
$$

### 7.4.3 Conjugate beam method

The method uses the formal analogy between the differential equation of the deformed axis:

$$
\frac{d^{2} w}{d x^{2}}=\frac{d \varphi}{d x}=-\frac{M}{E I}
$$

and the differential relations between stresses and loads (from statics):

$$
\frac{\mathrm{d}^{2} \mathrm{M}}{\mathrm{dx}^{2}}=\frac{\mathrm{dV}}{\mathrm{dx}}=-\mathrm{p}
$$

We can formally compare:
The displacement $w$ with the moment $\bar{M}$
The rotation (slope) $\varphi$ with the shear force $\bar{V}$
The external load with $\frac{M}{M_{0}}$
This load $\mathrm{p}=\frac{\mathrm{M}}{\mathrm{EI}}$ will action upon a fictitious beam, called conjugate beam. Following the analogy made before, we may define:

The conjugate beam is a fictitious beam which accomplish in stresses (bending moment $\bar{M}$ and shear force $\bar{V}$ ) the conditions accomplished by the real beam, in displacements (deflection $w$ and rotation $\varphi$ ).

Corresponding real and conjugate beams are shown below:

## Real beam

## Conjugate beam

From the above comparisons, we can state two theorems related to the conjugate beam:

Theorem 1: The rotation (slope) $\varphi$ at a point in the real beam is numerically equal to the shear force $\bar{V}$ at the corresponding point in the conjugate beam.

Theorem 2: The displacement $w(o r v$ ) of a point in the real beam is numerically equal to the bending moment $\bar{M}$ at the corresponding point in the conjugate beam

We shall exemplify the method for the same examples illustrated in the previous paragraph:

For the cantilever loaded by the concentrate force Pacting in the free end:

$$
\begin{gathered}
w_{\text {max }}=w_{B}=\bar{M}_{B}=\frac{1}{2} \frac{P l}{E I} l \cdot \frac{2}{3} l=\frac{P l^{3}}{3 E I} \\
\varphi_{\text {max }}=\varphi_{B}=\bar{V}_{B}=\frac{1}{2} \frac{P l}{E I} l=\frac{P l^{2}}{2 E I}
\end{gathered}
$$

For the cantilever loaded by the uniformly distributed force $q$ on the entire length:

$$
\begin{gathered}
w_{\max }=w_{B}=\bar{M}_{B}=\frac{1}{3} \frac{q l^{2}}{2 E I} l \cdot \frac{3}{4} l=\frac{q l^{4}}{8 E I} \\
\varphi_{\max }=\varphi_{B}=\bar{V}_{B}=\frac{1}{3} \frac{q l^{2}}{2 E I} l=\frac{q l^{3}}{6 E I}
\end{gathered}
$$

For the simple supported beam loaded by the uniformly distributed force $q$ on the entire length:

$$
w_{\max }=w\left(\frac{l}{2}\right)=\bar{M}\left(\frac{l}{2}\right)=\frac{2}{3} \cdot \frac{q l^{2}}{8 E I} \cdot \frac{l}{2} \cdot \frac{l}{2}-\frac{q l^{3}}{24 E I} \cdot \frac{3}{8} \cdot \frac{l}{2}=\frac{5 q l^{4}}{384 E I}
$$

$$
\varphi_{\max }=\varphi(0)=\bar{V}(0)=\frac{q l^{3}}{24 E I}
$$

### 7.5 APPLICATIONS TO UNIAXIAL BENDING WITH SHEARING

7.5.1 For the simple supported beam with the static scheme and the cross section from the figure bellow calculate:
a. geometrical characteristics
b. diagrams of stresses
c. the strength verification at bending ( $\sigma_{x \max }=2100 \mathrm{daN} / \mathrm{cm}^{2}$ ) and the normal stress diagram $\sigma_{\mathrm{x}}$
d. in section $A^{\prime}\left(A\right.$ left) the shear stress diagram $\tau_{x}$ with the significant values

The diagrams of stresses:

The critical section at bending is section $\mathrm{C}^{\prime}$ ( C left), where $\mathrm{M}_{\mathrm{y} \text { max }}=-237.5 \mathrm{kNm}$. With the second moment of area $\mathrm{I}_{\mathrm{y}}=62040 \mathrm{~cm}^{4}$, the maximum normal stress:

$$
\begin{aligned}
& \sigma_{x \max }=\frac{M_{y \max }}{I_{y}} z_{\max }=\frac{\left(-237.5 \times 10^{4}\right)}{62040} 47.08=1802 \frac{\mathrm{daN}}{\mathrm{~cm}^{2}}<2100 \frac{\mathrm{daN}}{\mathrm{~cm}^{2}} \\
& \sigma_{x \text { min }}=\frac{\left(-237.5 \times 10^{4}\right)}{62040}(-23.12)=885 \frac{\mathrm{daN}}{\mathrm{~cm}^{2}}
\end{aligned}
$$

In section $A^{\prime}$ the shear force $V_{z \text { max }}=-100 \mathrm{kN}$
$\tau_{\mathrm{xz} \max }=\frac{V_{z} S_{y}(z)}{b_{z} I_{y}}=\frac{100 \cdot 10^{2}(47.08 \cdot 1 \cdot 2 \cdot 47 \cdot 08 / 2)}{1.2 \cdot 62040}=178.64 \frac{\mathrm{daN}}{\mathrm{cm}^{2}}$
$\tau_{\mathrm{xz} 1-1}=\frac{100 \cdot 10^{2}(80.4 \cdot 15.3)}{1.2 \cdot 62040}=165.2 \frac{\mathrm{daN}}{\mathrm{cm}^{2}}$
$\tau_{\mathrm{xz} 2-2}=\frac{100 \cdot 10^{2}(8.85 \cdot 1.6 \cdot 18.695)}{1.6 \cdot 62040}=26.7 \frac{\mathrm{daN}}{\mathrm{cm}^{2}}$
$\tau_{\text {xy } 3-3}=\frac{100 \cdot 10^{2}(10.2 \cdot 1.6 \cdot 18.02+16.8 \cdot 1.35 \cdot 13.595)}{1.35 \cdot 62040}=71.9 \frac{\mathrm{daN}}{\mathrm{cm}^{2}}$
$\tau_{\text {xy } 4-4}=\frac{100 \cdot 10^{2}(10.2 \cdot 1.6 \cdot 18.02)}{1.35 \cdot 62040}=35.1 \frac{\mathrm{daN}}{\mathrm{cm}^{2}}$
7.5.2 For the simple supported beam with the static scheme and the cross section from the figure bellow calculate:
a. geometrical characteristics
b. diagrams of stresses (function the load parameter $q$ )
c. the load parameter $q$ if $\sigma_{x \max }=2200 \mathrm{daN} / \mathrm{cm}^{2}$ and then the normal stress diagram $\sigma_{x}$
d. in section A" (A right) the shear stress diagram $\tau_{\mathrm{x}}$ with the significant values

The diagrams of stresses (function the load parameter $q$ ):

The critical section at bending is where $\mathrm{M}_{\mathrm{y} \text { max }}=3.125 \mathrm{q}$
With the second moment of area $\mathrm{I}_{\mathrm{y}}=20969 \mathrm{~cm}^{4}$, the maximum normal stress:

$$
\sigma_{x \max }=\frac{M_{y \max }}{I_{y}} z_{\max }=\frac{\left(3.125 \mathrm{q} \times 10^{4}\right)}{20969} 19.04=2200 \frac{\mathrm{daN}}{\mathrm{~cm}^{2}}
$$

From the above equation, $\underline{q}=77.5 \mathrm{kN} / \mathrm{m}$

$$
\sigma_{x \min }=\frac{\left(3.125 \cdot 77.5 \times 10^{4}\right)}{20969}(-13.36)=-1543 \frac{\mathrm{daN}}{\mathrm{~cm}^{2}}
$$

In section A" the shear force $\mathrm{V}_{\mathrm{z} \text { max }}=193.75 \mathrm{kN}$

$$
\begin{aligned}
& \tau_{\mathrm{xz} \max }=\frac{V_{z} S_{y}(z)}{b_{z} I_{y}}=\frac{193.75 \cdot 10^{2}(17.84 \cdot 1 \cdot 17.84 / 2+1.2 \cdot 10 \cdot 18.44)}{1 \cdot 20969}=351.5 \frac{\mathrm{daN}}{\mathrm{~cm}^{2}} \\
